Large Nabothian Cyst: Manifestation with Pelvic Organ Prolapse in a Nulliparous Patient

Büyük Nabothi Kisti: Nullipar Hastada Pelvik Organ Prolapsusa Neden Olan Olgu

Nabothian Cyst Caused Pop

Abstract
Pelvic organ prolapse (POP) is described as the herniation of pelvic organs. POP generally occurs at postmenopausal age. Multiparity, increased intraabdominal pressure (e.g., bearing heavy weights, exerting physical effort), obesity, advanced age, menopause, prolonged labor, and smoking constitute prevailing risk factors of POP. It is seen rarely in nulliparous women. The main risk factors in nulliparous women are inherent defects in pelvic support. Nabothian cysts are benign entities in nature. They usually dissolve spontaneously and do not cause any clinical symptoms in routine practice. Nabothian cysts that cause POP are very rare in clinical practice. In this case report, we present the management of a large nabothian cyst causing POP in a 20-year-old patient without any prior intercourse.

Introduction
Pelvic organ prolapse (POP) is the herniation of pelvic organs to or beyond the vaginal wall and generally occurs at postmenopausal age (1,2). Weakness of pelvic muscles, connective tissues, and pelvic fascia may cause the prolapse. In apical compartment prolapse, the apex of the vagina descends into the lower vagina. Pelvic masses might be a reason for prolapse as well (3). Multiparity, increased intraabdominal pressure (e.g., bearing heavy weights, exerting physical effort), obesity, advanced age, menopause, past hysterectomies, past labor, prolonged labor, and smoking are risk factors for POP(1,4). In the nulliparous young age population, prevalence is about 2%. The main risk factors are inherent defects in pelvic support (Ehler-Danlos syndrome, congenital shortness of vagina, and deep uterovesical and uterorectal pouches) (5). Additionally, a nabothian cyst might rarely lead to prolapse of genital organs in nulliparous women.

In this report, we describe the excision of a large nabothian cyst in a 20-year-old patient without any prior intercourse.

Case Report
A 21-year-old female patient without any prior intercourse presented with a complaint of a smooth-surfaced mass protruding out of her vagina (Figure 1). The first time she discovered a mass protruding out of the vagina was around 2 years previously. She had no medical conditions in her medical history and no problem in her family history. General physical and systemic examinations were normal. During the inspection of genitals at the lithotomy position, the cervix was detected to pass 1 cm beyond the hymeneal line and there was a cystic mass with dimensions approximately 5x4 cm which originated from the cervix (Figure 2). Ultrasound exam showed that the uterus and ovaries were normal. After the initial assessment, the patient gave her consent for surgical removal. The large cystic mass was excised from the cervix under spinal anesthesia (Picture 3). Inside, the mass was completely filled with a white mucinous substance (Picture 4). After the cystectomy the cervix was elevated 2 cm up from the hymen so prolapse surgery was no longer needed. After the procedure, the patient was discharged at postoperative 1st day. Prolapse in the pelvic organs was not observed at the follow-up visit 4 weeks after the surgery. Histopathological examination revealed a nabothian cyst.

Discussion
A nabothian cyst is a benign, mucus filled cyst of the cervix and generally occurs at reproductive age. The size of the cysts may vary from microscopic dimensions to several centimeters. Most of them are asymptomatic and may appear translucent or opaque (5,6).

Nabothian cysts usually disappear without intervention. The main indications for surgery are size-related symptoms such as pain, feeling of pressure in the vagina, and prolapse. The most common period to encounter a nabothian cyst in a woman is menopausal age. It may be seen rarely in nulliparous or women with an intact hymen. Non-obstetric risk factors in young women for symptomatic pelvic organ prolapse: deficient connective tissue, high body mass index (BMI), family history.
of prolapse, asthma and chronic cough, chronic constipation, straining in defecation, variations of anatomy, and collagen synthesis and structure.(7).

Large nabothian cysts may cause prolapse and as their size grows, they require histopathological evaluation to rule out any malignant process (8).

Additionally, uterine prolapse may lead to urinary retention and subsequently this may lead to obstruction during labor or hydrenephrosis(9).

In nulliparous women and in women with an intact hymen, POP is seen quite rarely. There is one other case in the literature (5).

As this study and our report suggest, cystectomy should be the first step and a decision for a sling operation might be made according to the degree of POP after the cystectomy surgery.

In patients presenting with pelvic organ prolapse, it should be kept in mind that a benign or malignant cervical mass might accompany the situation and the decision to perform a surgical intervention with the purpose of correcting the prolapse should only be made after the cervical mass is totally removed.
