Abstract
Spontaneous rupture of ovarian dermoid cyst and chronic abdominal spillage of its content is a very uncommon condition, which causes granulomatous peritonitis and can be confused with peritoneal carcinomatosis. Here is presented such a case of ruptured dermoid cyst causing chronic granulomatous peritonitis with radiologic findings mimicking peritoneal carcinomatosis.

**Introduction**

Ovarian dermoid cysts are common lesions, accounting for up to 10–25% of all ovarian neoplasms [1]. Reported complications include torsion (16%), rupture (1–4%), malignant transformation (1–2%), infection (1%), invasion into adjacent viscera and autoimmune hemolytic anemia (<1%). The spontaneous rupture into adjacent viscera is one of the least common complications [2]. Here is presented a case of ruptured ovarian dermoid cyst with granulomatous peritonitis, with radiologic findings mimicking peritoneal carcinomatosis.

**Case Report**

A 54-year-old lady was referred to our clinic for further assessment of mild abdominal pain, fatigue and intra-abdominal free fluid. The patient had no operation history. Oral informed consent was obtained from the patient. Abdominal computed tomography (CT) revealed intra-abdominal free fluid and diffuse peritoneal infiltrative lesions (with 3.5 cm thickness), which is considered as "omental cake" (Figure 1).

No calcification or cystic lesions were found. According to these findings, our first impression as diagnosis was peritoneal carcinomatosis. Laboratory work-up revealed high serum CA125, carcinoembryonic antigen CEA and CA19-9 levels (109 U/mL, 12.1 mg/mL and 23.576 U/mL, respectively). She had leukocytosis (14.20 K/mm³) with a serum CRP level of 107.30 mg/L. MRI was performed for differential diagnosis: an amorphous, thin-walled, cyst-like right adnexal lesion of 9.8x7.0x5.5 cm was detected. The margins of lesion were discontinuous. Additionally restricted diffusion of omentum on diffusion weighted images (DWI), some fat-fluid levels on T2WI and foamy appearance of fat signals were found on MRI (Figure 2,3).

High lymphocyte count was detected in the peritoneal fluid on peritoneal irrigation. Surgery revealed a ruptured right ovarian dermoid cyst, peritonitis and bowel adhesions. Omentectomy, total abdominal hysterectomy and salpingo-oophorectomy were performed. The frozen biopsy sections of peritoneum and right ovary were reported to be benign. Early postoperative course and 18-month follow-up of the patient was eventless.

**Discussion**

The typical radiologic finding of dermoid cyst is intratumoral fat. The most common ultrasound finding is a cystic mass with an echogenic tubercule due to hair, teeth, and fat [3]. At CT, intratumoral fat shows negative attenuation [4]. At MRI, intratumoral fat shows hyperintense on T1-weighted images, and drop on fat-saturated T1-weighted images. In addition to intratumoral fat, calcification is also commonly seen in ovarian dermoid cysts, but it does not always indicate ovarian dermoid cyst. Therefore, the presence of intratumoral fat is important in the diagnosis of ovarian dermoid cysts [3,5].

The ovarian dermoid cysts have keratinoid content, therefore, they have been shown to exhibit lower ADC values than any other benign or malignant adnexal lesion, a characteristic that may help diagnose lesions with a paucity of fat [6]. We detected restricted diffusion on ADC maps in the both lesion and omental areas, therefore, we thought malignancy.

Spontaneous rupture is an extremely rare complication of dermoid cyst (also known as mature cystic teratoma). Because, it usually has a thick capsule. The reported causes of rupture are torsion with infarction of the tumor, infection, malignancy and rapid growth of the cyst, direct trauma, or prolonged pressure during pregnancy [7]. At ultrasound, CT and MRI, the integrity of the tumor wall should be carefully evaluated for accurate diagnosis of a ruptured ovarian dermoid cyst [8]. Similar to these findings, the integrity of the tumor wall in our case was disrupted.

There has been two possible clinic presentations for ruptured dermoid cysts reported in the literature. First presentation is spillage of tumor contents into the abdominal cavity due to rupture, it can lead severe acute chemical peritonitis. Second, chronic granulomatous peritonitis due to chronic cyst content leak is characterized by multiple small white peritoneal lesions, dense adhesions, and ascites mimicking carcinomatosis or tuberculous peritonitis [9].

Chronic granulomatous peritonitis usually has unusual radiologic findings: ascites and omental infiltration. These findings simulate carcinomatous or tuberculous peritonitis. Ovarian and gastrointestinal system malignancies usually manifest with ascites and peritoneal carcinomatosis.

Serum tumor markers (CA19-9, CEA, CA 125) tend to be high in gastrointestinal system lesions. In our case, high tumor mark-

ers, ascites, “omenta cake” appearance were suggestive of a malignant tumor.

As a very rare entity, chronic granulomatous peritonitis due to ruptured ovarian dermoid cyst can be easily confused with peritoneal carcinomatosis. Mild chronic abdominal pain, a very thin cyst wall remnant, fat-fluid levels, and foamy fat signals on MRI are important clues for dermoid cyst rupture and chronic spillage. Hence, MRI is highly important to make the differential diagnosis.
